Abstract

Country risk premia can substantially affect macroeconomic dynamics. We concentrate on one of their most important determinants - a country’s net foreign asset position and - in contrast to the existing research - investigate its nonlinear link to risk premia. The importance of this particular nonlinearity is twofold. First, it allows to identify the NFA level above which the elasticity becomes much (possibly dangerously) higher. Second, such a nonlinear relationship is a standard ingredient of DSGE models, but its proper calibration/ estimation is missing. Our estimation shows that indeed the link is highly nonlinear and helps to identify the NFA position where the nonlinearity kicks in at -70% to -80% of GDP. We also provide a proper calibration of the risk premium - NFA relationship used in DSGE models and demonstrate that its slope matters significantly for economic dynamics in such a model.

**JEL:** C23, E43, E44

**Keywords:** Risk premium, PSTR model, open economy DSGE model
1 Introduction

Country risk premia have the ability to substantially affect macroeconomic dynamics in open economies. This is particularly the case when spreads shoot up (as they did for instance in Greece in 2012) effectively cutting the economy off from borrowing. What stands out in this context is the potential of risk premia to generate a debt spiral. If a country is highly indebted investors may fear about its solvency. As a consequence risk premia could rise, increasing debt servicing costs and, as a consequence, possibly further increasing foreign debt. This mutual relationship may not only have bearing consequences for indebted countries, but also make the relationship between foreign debt and risk premia highly nonlinear.

Given their importance, risk premia have received substantial attention in the literature, both empirical and structural (DSGE). Empirical papers concentrate on finding the determinants of country risk. The list of related papers is long and includes i.a. Ferrucci (2003); Ciocchini et al. (2003); Baldacci and Kumar (2010) and Bellas et al. (2010). Foueijieu and Roger (2013) provide an extensive literature review on the topic. These studies point at a number of important risk premium determinants, including the fiscal balance and debt, foreign debt or net foreign assets, political stability, exchange rate volatility, financial sector characteristics, the ability to borrow in domestic currency or external liquidity conditions. Several papers point out the crucial role of foreign debt, however it usually enters the estimated equations in a linear fashion. To motivate our case we present on Figure 1 the scatterplot of our two main data series - the interest rate differential between a country’s and the United States long term bonds and its net foreign asset position. The non-linear relationship is evident, although one should remember that this picture does not control for other, possibly important factors.

In the DSGE literature risk premia play a very important role - following Schmitt-Grohe and Uribe (2003) endogenous risk premia, driven by a country’s net foreign asset (NFA) position are used to pin-down foreign debt and allow for solving DSGE models of small, open economies (e.g. Adolfson et al. 2007; Christoffel et al. 2008; Garcia-Cicco et al. 2010; Justiniano and Preston 2010; Benczur and Konya 2015). The source of the problem is that without an endogenous premium a small, open economy could borrow any amount at the world interest rate.

As already explained, the NFA position plays a crucial role in both streams of the literature. However, both streams miss something important. The empirical literature mentioned above has so far concentrated on modeling a linear relationship between the risk premium and NFA (or gross foreign debt) position. This misses the crucial problem of nonlinearities. The DSGE literature in contrast, usually focuses on a nonlinear (e.g. exponential)
relationship, however it neglects its calibration.\textsuperscript{1} This may bias the models dynamics.

In this paper we focus our attention on the nonlinear relationship between the risk premium and the NFA position of a country. We see two important contributions, one for policy and one for modeling. Both are not offered by linear models. First, from the policy perspective our estimates help to determine the regions where the premium becomes particularly elastic to debt and - as a consequence - the economy risks falling into a debt spiral. From the modeling perspective, we offer a ready-to-use calibration of the risk premium - NFA relationship that can be applied in DSGE models. Of course one has to bear in mind that the relationship offers rather a shortcut than a structural linkage. From this perspective our results could also be considered as motivation to provide a structural derivation of this link in the DSGE literature. Our results could then serve as a check whether the derived link is in line with empirics.

The paper consists of two parts. In the first we estimate a nonlinear model of the risk premium, focusing primarily on its relationship with the NFA position. We collect data for 41 advanced and emerging economies and show that indeed the link is highly nonlinear. For positive and mildly negative NFA positions the risk premium to NFA elasticity is slightly negative. However, once NFA worsens further the elasticity decreases substantially. We identify the level at which strongest nonlinearities kick in at approximately -70\% to -80\% NFA to GDP ratio. At this level of foreign debt the semi-elasticity of spreads with respect to NFA increases more than twenty-fold compared to normal times. As a consequence a country can be caught in a debt trap.

The second part adapts the estimated relationship to the structure of a typical DSGE model. Such relationships have for a long time constituted an important ingredient of small open economy DSGE models. However, their calibration was supposed to provide model stability rather than reflect the elasticities found in the data. We fill this gap. Moreover, we show on the basis of a standard two-economy DSGE model that taking into account the nonlinear risk premium - NFA relationship has important consequences. First, it allows to take into account diverging rates of time preference in a way that is consistent with a well parametrized steady state. Second, we show that model dynamics and stochastic properties differ significantly depending on steady state debt.

The rest of the paper is organized as follows. Section 2 discusses the data and Section 3 our econometric procedure and results. Section 4 discusses the application of our results for DSGE modeling. Section 5 concludes.

\textsuperscript{1}A notable exception is Garcia-Cicco et al. (2010) who estimate an RBC model with risk premium on a 105-years long time series for Argentina. The estimated relationship suggests that if the stock of external debt increases by one percentage point of GDP then the country premium increases by over half a percentage point. The coefficient is several orders of magnitude larger than the one calibrated by Schmitt-Grohe and Uribe (2003).
2 Data

We collect annual data for 41 advanced and emerging economies (see Table 1 for a list). Our panel extends from 1991 to 2014, is however unbalanced due to limited availability of data on long-term interest rates. Our dependent variable is defined as the difference between a country’s long-term interest rate and the rate for United States. The data comes from International Financial Statistics and Bloomberg and in most cases represents the yield on 10-year government bonds. For a few countries, where 10-year bonds were missing we approximate the spread using 5-year bonds.

Following the literature we use the following set of explanatory variables:

- Net foreign asset to GDP ratio - the data is drawn from the IMF’s database constructed for the External Balance Assessment exercise (IMF, 2013). The series is an update on the NFA statistics provided by Lane and Milesi-Ferretti (2001).
- General government gross debt to GDP ratio (source: World Economic Outlook)
- General government net lending to GDP ratio (source: World Economic Outlook)
- VXO (source: Chicago Board of Trade)
- Foreign exchange reserves to GDP ratio (source: World Development Indicators)
- CPI inflation (differential to US inflation) (source: World Development Indicators)
- Current account balance to GDP ratio (source: World Economic Outlook)
- GDP per capita (at purchasing power parity) relative to the US (source: World Economic Outlook)

It has to be emphasised that our dependent variable is a proxy rather than a direct measure of the country risk premium. Beyond country risk this variable may for instance contain an expected inflation component or exchange rate risk. Moreover, formally it refers to sovereign debt and as such does not cover the private sector. Data limitations are the main reason, why (in line with much of the literature) we need to make such compromise. We believe that our control variables (like the inflation differential, or fiscal variables) help to reduce the problem.
3 Model and estimation

3.1 Econometric approach

We assume a non-linear relationship between a country’s risk premium and the value of its net foreign assets. In particular we expect that the semi-elasticity of the risk premium with respect to its NFA position increases as the latter variable falls. We capture this non-linear relationship using a panel smooth transition regression (PSTR) model as proposed initially by Granger and Teräsvirta (1993) and Teräsvirta (1994) for time series and cross sectional data and extended by González et al. (2005) for panel data. The model allows for switching between two regimes, which depend on the level of the country’s external indebtedness.

We start from a general form of non-linearity and test for the distribution of the transition function. Therefore we formulate a fixed effects PSTR model which takes a general form:

\[ y_{it} = \mu_i + \delta_1 NFA_{it} + G(s_{it}; \gamma, c) \delta_2 NFA_{it} + \beta' x_{it} + u_{it}, \]  

where \( G(s_{it}; \gamma, c) \) is a transition function allowing for the non-linear relationship between the country’s risk premium \( y_{it} \) and its net foreign assets position \( (NFA_{it}) \). Moreover \( x_{it} \) stands for the vector of other variables affecting the risk premium (as listed in Section 2), \( \mu_i \) express the fixed individual effects and \( u_{it} \) are the error terms. We investigate two alternative transition functions usually proposed in the literature, the logistic function:

\[ G(s_{it}; \gamma, c) = (1 + \exp\{-\gamma(s_{it} - c)\})^{-1}; \quad \gamma > 0 \]  

and the exponential function:

\[ G(s_{it}; \gamma, c) = 1 - \exp\{-\gamma(s_{it} - c)^2\}; \quad \gamma > 0. \]  

The variable \( s_{it} \) in (2) and (3) is the transition variable, \( c \) is a threshold parameter, and \( \gamma \) is a transition parameter, which measures the speed of transition from one regime to the other. The restriction \( \gamma > 0 \) is an identifying restriction.

The transition functions described by (2) and (3) are bounded between 0 and 1. It means that the parameter measuring the semi-elasticity of the risk premium with respect to the net foreign asset position may vary between \( \delta_1 \) and \( \delta_1 + \delta_2 \) along with the transition variable \( s_{it} \). The logistic function (2) approaches zero for very large negative values of the transition variable and approaches one for very large positive values. The exponential function (3) unity for very large both positive and negative values of the transition variable \( s_{it} \) and is close to zero when \( s_{it} \) is equal to the value of the threshold parameter \( c \). As a consequence our functional form allows to accommodate a wide range of shapes.
We assume that the semi-elasticity of the risk premium with respect to the country’s NFA position depends on its NFA stock. Therefore the transition variable \( s_{it} \) in equation (1) reflects the net foreign assets position and the PSTR model boils down to:

\[
y_{it} = \mu_i + \delta_1 NFA_{it} + G(NFA_{it}; \gamma, c) \delta_2 NFA_{it} + \beta' x_{it} + u_{it},
\]

(4)

If the PSTR model with the logistic transition function (2) is validated, it implies that the changes in external debt influence the risk premium to a different extent when the debt is low and when it is high. On the other hand, when the exponential transition function (3) is validated the semi-elasticity of the risk premium with respect to external debt changes (probably rises) as debt increases but after exceeding a certain debt level it returns to the initial level. While such shape seems a priori somewhat less likely, we do not want to exclude this possibility. Low elasticities for deeply negative NFA positions could for instance results from investors expectations of international financial support programs or a decision of debt restructuring not yet evidenced in NFA data.

Figures 2 and 3 present examples of possible relationships between the risk premium and NFA for the logistic and exponential transition functions. Note that estimation of the PSTR model allows not only to determine the type of transition function but also the speed of transition between the regimes.

We proceed in two steps adopting the method proposed by Escribano and Jordá (2001), which allows to distinguish between two alternative transition functions: the logistic and the exponential one. First we test for the presence of general PSTR non-linearity in the form proposed by model (4) against the linear panel model. Model (4) is linear if \( \gamma = 0 \) or \( \delta_2 = 0 \). However under both hypotheses the PSTR model contains unidentified parameters and the respective tests are non-standard (see Hansen, 1996 and Luukkonen et al., 1988 for discussion). Therefore we approximate the non-linearity in model (4) by the second order Taylor series expansion of the PSTR model with exponential transition function around \( \gamma = 0 \), which is the auxiliary regression for the proposed Escribano and Jorda test:

\[
y_{it} = u_i + \delta NFA_{it} + \beta' x_{it} + \lambda_1 NFA_{it}^2 + \lambda_2 NFA_{it}^3 + \lambda_3 NFA_{it}^4 + \lambda_4 NFA_{it}^5 + u_{it},
\]

(5)

The null hypothesis of linearity is:

\[ H_0 : \lambda_1 = \lambda_2 = \lambda_3 = \lambda_4 = 0 \]

\footnote{González et al. (2005) propose the testing procedure where the non-linear (logistic) transition function in equation (1) is approximated by the first order Taylor series expansion. Since we would like to test the general non-linearity first and then select between the transition functions we do not follow this procedure, which implies ex ante the logistic distribution of the transition function.}
and may be tested using Wald or LM type statistics.

Once the linearity is rejected the next step is to select between the PSTR model with the logistic or exponential transition functions. Therefore following Escribano and Jordá (2001) we test two hypotheses:

\[ H_{0L} : \lambda_1 = \lambda_3 = 0 \]

and

\[ H_{0E} : \lambda_2 = \lambda_4 = 0 \]

We choose the PSTR model with logistic (exponential) transition function if the minimum p-value is obtained for \( H_{0L} (H_{0E}) \), conditionally on rejecting linearity.

After the transition function has been selected we estimate the parameters of the non-linear model (4). For the smooth transition regression model with fixed effects González et al. (2005) propose the application of the within estimator and non-linear least squares (NLS). As for the linear within estimator we remove first the fixed effects from the model by subtracting the individual specific means from the data. Then we apply the non-linear least squares estimator to the transformed variables.

The algorithm which allows to compute the within estimator for the panel STR model differs slightly as compared to the linear case. Since the model is non-linear the values of some explanatory variables in (4) depend on the parameters of the transition function \( c \) and \( \gamma \). Therefore respective explanatory variables and their individual specific means are varying with the iterative estimation of the parameters of the transition function. For that reasons they have to be recomputed at each iteration (see González et al., 2005 for details).

### 3.2 Estimation results

We start the analysis by specifying the linear model first. We estimate a static fixed effects model with the standard errors corrected for the presence of autocorrelation and remaining heteroscedasticity. The estimation results are collected in Table 2. In the first column we present the risk premium model including the whole initial set of potential explanatory variables. Some of them prove to be statistically insignificant. In particular we find the risk premium not to be affected by the value of foreign exchange reserves as related to country’s GDP. Moreover the yield differential is not influenced by the changes in the current account balance.

This latter result combined with the statistical significance of the net foreign assets position allow concluding that the investors in the assessment of the country’s risk premium pay more attention to the stock of the external indebtedness rather than to its changes. All other explanatory variables included initially in the risk premium model have a statistically
significant impact on the yields differential.

In the second column of Table 2 we show the final specification of the linear fixed effects model with statistically significant explanatory variables only. Our estimates seem consistent with economic intuition. The risk premium depends positively on the general government debt and on the inflation differential, which partially captures the difference in the short term nominal interest rates. We also observe a positive relationship with exchange rate volatility. Furthermore the estimation outcome shows that the yields differential decreases as the real convergence process occurs. We evidence that the progress in the stage of convergence expressed by the relative GDP per capita limits a country’s risk premium. The premium is also negatively affected by the general government balance. It is worthy to note that the risk premium is influenced by both the government debt and the fiscal deficit. Interestingly in contrast to the external indebtedness the investors account for the stock but also the flow fiscal variables.

At this point the issue of potential endogeneity of the explanatory variables has to be raised. As far as the fiscal variables are concerned this problem seems to be negligible since the change in long-term yields differential affects the current level of debt and fiscal deficit only to minor extent. That is because the change in long-term yields influences only the costs of the debt service for the new issuance of the long-term sovereign bonds, which constitutes usually only a small part of the whole debt service costs. We also do not expect the endogeneity problem in case of the net foreign assets position since we use the NFA stock measured at the end of the preceding year. We believe that the only explanatory variable which may be endogenous in our model is the variable representing the exchange rate volatility. To address the problem of potential endogeneity we instrument this variable by its first differences, its squares as well as by the VXO index measuring the level of risk aversion on the global financial markets.

The results for the model with instrumented exchange rate volatility variable have been collected in the third column of Table 2. The Sargent J-test fails to reject the hypothesis about the proper choice of instruments at the 5% significance level. The results for the model with instrumental variables do not differ substantially as compared with the estimation results for the model estimated with OLS presented in column 2. Only the coefficient estimate for exchange rate volatility is slightly smaller. The choice of the estimation method does not alter the coefficient estimates for other variables.

As a next step we test for the potential non-linearity in the relationship between the net foreign assets position and the country’s risk premium using the algorithm described in

---

3Gumus (2013) argues that the effect of exchange rate fluctuations on the country’s default risk priced in the yields on sovereign bonds may be substantial in particular in case of emerging economies with relatively high share of foreign currency denominated debt while the exchange rate movements increase the costs of debt service raising the probability of country’s default.
Section 3. First we estimate the second order Taylor series expansion for the PSTR model with exponential transition function, which is the auxiliary regression for this test. We verify the joint statistical significance of the variables being the subsequent powers of NFA from the second to the fifth power in equation (5). We collect the outcomes of this test in Table 3. We follow this testing procedure for the model estimated with OLS (columns 1 and 2 in Table 3) and for the alternative model, in which the exchange rate volatility has been instrumented (columns 3 and 4). The appropriate test statistics allow rejecting the null hypothesis of linearity in favor of general STR type non-linearity at any conventional significance level for both investigated models.

Once the linearity has been rejected we select further between the logistic and exponential transition function in the PSTR model as described in Section 2. The outcome of this test for our basic fixed effects model estimated with OLS (columns 1 and 2 in Table 3) as well as with IV method (columns 3 and 4 in Table 3) clearly suggests the choice of the logistic function as the appropriate transition function. The p-values for the respective hypotheses are significantly lower than for the hypotheses implying the validity of the exponential function.

Thus we choose the logistic function as the transition function in the PSTR model.

Accordingly we derive the coefficients of the model with OLS and with the IV method to check for potential endogeneity of the exchange rate volatility. We use the same instruments as in the previous steps: first differences of the exchange rate volatility, its squares and the VXO index. The estimation results for both models are presented in Table 4.

In the first column we present the fixed effects model estimated with non-linear OLS while in the second column we show the fixed effects model estimated with non-linear LS with instrumental variables. Moreover in the third and fourth columns we show the results for the model including the year dummies. The results validate the choice of the PSTR model with the logistic transition function. The parameter reflecting the non-linear impact of the NFA position on the risk premium is statistically significant at 5% significance level.

As pointed out in Section 3 the choice of the logistic transition function implies that the (negative) parameter measuring the influence of the net foreign assets stock on the yields differential decreases as NFA declines. The results for the fixed effects model estimated with non-linear OLS (column 1 in Table 4 ) show that the impact of the changes in NFA stock on the country’s risk premium increases significantly (in modulus) as NFA approaches ca -74% of the country’s GDP. For NFA values lower than this threshold level the worsening in the NFA position by 10 p.p. results in an increase of the risk premium by ca. 19 bps. It is worth to remind that this effect is almost twice as large as for the linear model discussed previously. For NFA levels below the threshold the semi-elasticity of the risk premium is only negligible. The improvement in NFA stock by 10 p.p. results in a decrease of risk premium by only 0.7 bps (the sum of coefficients $\delta_1 + \delta_2$ equals -0.07 – see Table 4). The semi-elasticities are
Model and estimation

presented on Figure 4.

In line with the literature our estimation confirms the impact of several other variables on the risk premium. The semi-elasticity of the risk premium with respect to inflation differential is 0.54 which means that the increase of country’s inflation relative to US inflation transmits to the long term yields differential only by a half (column (1) in Table 4). While this is much below the unit parameter that could be expect, one should remember that current inflation is probably an imprecise proxy for long term inflation expectations. The semi-elasticity of the public debt is relatively low and equals 0.017 – the growth of general government debt to GDP ratio by 1 p.p. raises the yields differential by 1.7 bps. The reaction of the investors to changes in the general government balance is stronger. The improvement of the fiscal balance by 1 p.p. reduces the yields differential by ca. 7 bps. However it is worth to note that both fiscal variables are correlated with each other because the improvement of the fiscal balance might lead to the reduction of the borrowing needs and furthermore to decrease of public debt. Hence the isolated impact of each of these variables may be stronger. Moreover the exchange rate volatility and the variable expressing the country’s GDP per capita level are also statistically significant with expected signs.

It is worth noting that the results for the fixed effects model estimated with instrumental variables are very close to the OLS estimates. The only slight difference concerns the parameter estimate related to exchange rate volatility being instrumented in the second model.

3.3 Robustness checks and extensions

We do a number of robustness checks and extensions of the baseline framework, but they do not change our main findings. Below, we report the two that we find most important.

First we extend the fixed effects PSTR model (5) for time (year) dummies to capture potential commons trends. The estimation results for this model are presented in the third and fourth columns of Table 4. The findings are similar to the basic model with the exception of the variable reflecting the fiscal balance, which proves to be statistically insignificant. The semi-elasticities of the risk premium with respect to the NFA position are only about 10% larger than in the basic models and remain statistically significant.

Second we check whether the threshold level of the NFA position (reflected by the constant term in transition function (2)) at which the foreign indebtedness starts affecting the country’s risk premium more seriously, may be different for advanced and emerging economies. In other words we verify the hypothesis that the investors are more tolerant in the assessment of country’s credit risk with respect to its level of foreign debt for developed rather than developing countries. To test this hypothesis we include into the PSTR model a dummy variable, which differentiates the threshold level of the NFA position between emerging and
advanced economies. The transition function in the PSTR model capturing this feature has then a following form:

\[ G(s_{it}; \gamma, c) = (1 + \exp\{-\gamma(s_{it} - c - c_1 \cdot AE_i)\})^{-1}; \quad \gamma > 0 \]  

(6)

where \( AE_i \) is a variable which takes the value of one for advanced economies and zero otherwise. The classification of the respective economies follows the IMF classification and has been included in Table 1.

The estimation results are presented in the fifth and sixth columns of Table 4. The dummy variable which differentiates the NFA threshold level between advanced and emerging economies proves to be statistically significant but the magnitude of its impact on the country’s risk assessment is rather small. The estimated threshold levels of the NFA positions for developed and emerging economies differ by only ca. 4.5% of GDP. In line with our expectations this level is higher for advanced economies and amounts to ca. 70% of GDP. The parameter estimates for other control variables in the extended model are very close to the numbers obtained in our basic model. All in all, these results lead to the conclusion that the perception of certain economy as being advanced or developing per se does not strongly affect the threshold level at which the non-linearity in country’s risk assessment kicks in.

4 Consequences for DSGE models

4.1 A simple rule

The relationship on which our study focuses - between the country risk premium and its net foreign asset position plays an important role in constructing and solving DSGE models. As explained in detail by Schmitt-Grohe and Uribe (2003), models of small open economies may suffer from indeterminacy. This is because in a standard framework nothing pins down the small open economy’s foreign debt level. Schmitt-Grohe and Uribe (2003) offer a number of solutions to this problem, i.a. endogenous discount factors, convex portfolio adjustment costs or a debt elastic country interest rate premium.

The last solution has been found particularly popular, several small open economy DSGE models have been solved by adding this feature (e.g. Adolfson et al. 2007; Christoffel et al. 2008; Justiniano and Preston 2010; Garcia-Cicco et al. 2010). The original specification, from which most future studies borrow is as follows:

\[ \rho_t = 1 + \psi \left( \exp(d_t - d) - 1 \right) \]

where \( \rho_t \) denotes the risk premium as specified in DSGE models (details below), \( d_t \) is the net foreign debt to GDP ratio, \( d_t \) its steady state level and \( \psi \) a positive parameter.

Under such a function foreign debt is pinned down in steady state and the positive slope of the function guarantees its stability around this level. What is problematic is the calibration. While the steady state debt can be usually recovered from the country’s data, things are more complicated when it comes to \( \psi \). For many countries there may not be enough volatility in the data to allow for a successful time series estimation. Even less promising seems finding the parameter via system estimation of the whole DSGE model. First, such estimation does usually not feature control variables which, as we show, are important determinants of the premium. Second, for technical reasons estimation of DSGE models is conducted for their linearized version. However, we have shown, that the relationship is strongly nonlinear.

In what follows we transform the estimated nonlinear OLS relationship so that it can be directly applied in DSGE models. The transformation takes into account the following issues.

• In contrast to our econometric specification, DSGE models usually do not feature control variables like exchange rate volatility. We keep them in the estimation to avoid biased parameters, but ignore them in the final specification.

• Most of the DSGE models under consideration are of quarterly frequency and the premium is expressed in gross terms. We adjust the parameters accordingly to make
4 Consequences for DSGE models

4.1 A simple rule

The relationship on which our study focuses - between the country risk premium and its net foreign asset position plays an important role in constructing and solving DSGE models. As explained in detail by Schmitt-Grohe and Uribe (2003), models of small open economies may suffer from indeterminacy. This is because in a standard framework nothing pins down the small open economy’s foreign debt level. Schmitt-Grohe and Uribe (2003) offer a number of solutions to this problem, i.a. endogenous discount factors, convex portfolio adjustment costs or a debt elastic country interest rate premium.

The last solution has been found particularly popular, several small open economy DSGE models have been solved by adding this feature (e.g. Adolfson et al. 2007; Christoffel et al. 2008; Justiniano and Preston 2010; Garcia-Cicco et al. 2010). The original specification, from which most future studies borrow is as follows:

\[ \rho_t = 1 + \psi (\exp(d_t - d) - 1) \]

where \( \rho_t \) denotes the risk premium as specified in DSGE models (details below), \( d_t \) is the net foreign debt to GDP ratio, \( d \) its steady state level and \( \psi \) a positive parameter.

Under such a function foreign debt is pinned down in steady state and the positive slope of the function guarantees its stability around this level. What is problematic is the calibration. While the steady state debt can be usually recovered from the country’s data, things are more complicated when it comes to \( \psi \). For many countries there may not be enough volatility in the data to allow for a successful time series estimation. Even less promising seems finding the parameter via system estimation of the whole DSGE model. First, such estimation does usually not feature control variables which, as we show, are important determinants of the premium. Second, for technical reasons estimation of DSGE models is conducted for their linearized version. However, we have shown, that the relationship is strongly nonlinear.

In what follows we transform the estimated nonlinear OLS relationship so that it can be directly applied in DSGE models. The transformation takes into account the following issues.

- In contrast to our econometric specification, DSGE models usually do not feature control variables like exchange rate volatility. We keep them in the estimation to avoid biased parameters, but ignore them in the final specification.

- Most of the DSGE models under consideration are of quarterly frequency and the premium is expressed in gross terms. We adjust the parameters accordingly to make
it compatible with models where for instance \( \rho_t = 1.025 \) is a 25 basis point premium expressed on quarterly basis.

- DSGE models usually contain a net foreign debt variable instead of net foreign assets. The variable is expressed relative to quarterly GDP.
- In the presented estimations NFA was measured at the end of the previous period. Accordingly \( d_t \) will denote foreign debt at the end of period \( t - 1 \).

Then our relationship is:

\[
\rho_t = 1 + d_t \left\{ \psi_1 + \psi_2 \left[1 + \exp \left( \psi_3 \left( d_t - \psi_4 \right) \right) \right]^{-1} \right\} \tag{7}
\]

This relationship is nonlinear an as such can be used directly for studying deterministic model dynamics. It should be noted, that given the relatively fast transition between the two regimes (see Figure 4) for stochastic purposes the relationship can be linearized around the appropriate steady state without much loss of accuracy. The only problematic area is the vicinity of our threshold debt ratio (300% of quarterly GDP). Then the relationship can be simplified to:

\[
\rho_t = 1 + \psi_5(d_t - d) \tag{8}
\]

where

\[
\psi_5 = \begin{cases} 
\psi_1 + \psi_2 & \text{for } d \ll 3 \\
\psi_1 & \text{for } d \gg 3 
\end{cases}
\]

The parameters of equations (7) and (8) after being slightly rounded are given in Table 5.

### 4.2 The model

A natural question emerges, whether and how these estimates matter for DSGE modeling. This will be analyzed on the basis of a standard two economy new Keynesian model. The model consists of two symmetric economies, both populated by households, intermediate and final good producers and a central bank. Households derive utility from leisure and consumption, can save in domestic and foreign bonds and accumulate capital. Producers use labor and capital rented from households to produce differentiated intermediate goods. These are exported or sent to the domestic market. At this stage prices are sticky a la Calvo in local (consumer) currency. Final goods are aggregated from domestic and imported goods and used for consumption and investment purposes. The central bank follows a Taylor rule. Below we present only problems of the domestic agents, problems of foreign agents are symmetric. Foreign variables are denoted with an asterix.
Households

Households work $n_t$, consume $c_t$ and accumulate domestic $B_t$ and foreign $B_t^*$ bonds remunerated at the central bank interest rates $R_t$ and $R_t^*$ respectively. Moreover, they own the capital stock $K_t$ which is rented to firms at the rate $R^K_t$ and depreciates at the rate $\delta$. A representative household $\iota$ maximizes lifetime utility:

$$\max U_t = E_t \sum_{i=0}^{\infty} \beta^i e^{\varepsilon_{u,t+i}} \left[ \left( c_{t+i}(\iota) - h c_{t+i-1} \right)^{1-\sigma} - A_n \left( n_{t+i}(\iota) \right)^{1+\varphi} \right]$$

subject to a sequence of budget constraints:

$$P_tC_t(\iota) + \frac{1}{R_t} B_{t+1}(\iota) + S_t \rho_t R^K_{t+1}(\iota) = W_t n_t(\iota) + R^K_t K_t(\iota) + B_t(\iota) + S_t B^*(\iota) + \Pi_t$$

and the law for capital accumulation

$$K_{t+1} = (1-\delta) K_t + \left[ 1 - \Gamma \left( \frac{i_t}{i_{t-1}} \right) \right] i_t$$

where $P_t$, $W_t$, $S_t$, $\Pi_t$ are, respectively the price of consumption goods, the nominal wage, the nominal exchange rate and dividends paid by imperfectly competitive intermediate goods producers. Further, $i_t$ denotes investments and $\Gamma(\bullet)$ denotes a quadratic investment adjustment cost. Moreover, $\beta$ denotes the agents discount rate and $A_n$ is the weight of labor in utility. The inverse of the intertemporal elasticity of substitution in consumption is denoted by $\sigma$ and $\varphi$ is the inverse Frisch elasticity of labor supply. Consumption is subject to external habit persistence $h$. We assume that the intertemporal preference shock $\varepsilon_{u,t}$ follows an AR(1) process with persistence $\rho_u$ and standard deviation of innovations $\sigma_u$. The international risk premium $\rho_t$ is assumed to follow (7).

We will not present all equilibrium conditions, only those referred to below. The first is the Euler consumption equation:

$$\frac{\lambda_t}{P_t} = \beta E_t \frac{\lambda_{t+1}}{P_{t+1}} R_t$$

and the second the uncovered interest rate parity condition:

$$E_t \frac{\lambda_{t+1}}{\pi_{t+1}} R_t = E_t \frac{\pi_{t+2} \lambda_{t+1} \rho_t R^*_t}{\pi_{t+1} q_t}$$

(13)
where \( \lambda_t \) denotes the marginal utility of household’s consumption, \( \pi_t \equiv \frac{P_t}{P_{t-1}} \) is inflation and \( q_t \equiv \frac{S_t P_t}{P_t} \) the real exchange rate.

**Producers**

There are two types of firms: intermediate goods producers and final good producers. Perfectly competitive final good producers purchase intermediate domestic and foreign goods and produce a final good \( \tilde{y}_t \) using the following technology

\[
\tilde{y}_t = \left[ \eta \left( \frac{1}{\nu} (y_{H,t})^{\frac{1}{\nu}} + (1 - \eta) \left( \frac{1}{\nu} (y_{F,t})^{\frac{1}{\nu}} \right) \right) \right]^{\mu} 
\]

(14)

where \( \eta \) is the home bias in consumption and \( \mu \) determines the elasticity of substitution between domestic and foreign goods while \( y_{H,t} = \left( \int_0^1 y_{H,t} (j)^{\frac{1}{\mu_H}} dj \right)^{\mu_H} \) and \( y_{F,t} = \left( \int_0^1 y_{F,t} (j)^{\frac{1}{\mu_F}} dj \right)^{\mu_F} \) are aggregates of domestic and foreign intermediate goods respectively. Parameters \( \mu_H \) and \( \mu_F \) determine the elasticities of substitution between their varieties.

Producers of intermediate goods act under monopolistic competition. They produce specific (differentiated) goods and sell them to final good producers at home and abroad. They solve the same cost minimization problem, however, have different pricing strategies for the domestic and foreign market. Local currency pricing is assumed, i.e. prices are sticky in the buyers currency. They produce using the following technology

\[
y_{H,t} (j) + y_{H,t}^* (j) = z_t k_t^a(j) (y_{H,t})^{\gamma} \]

(15)

where \( z_t \) denotes a productivity shock that follows an AR(1) process with persistence \( \rho_z \) and standard deviation of innovations \( \sigma_z \). Intermediate goods producers set their prices according to the Calvo scheme. In each period, each producer \( j \) receives with probability \( 1 - \theta_H ^* \) or \( 1 - \theta_H ^* \) a signal to reoptimize her price on the domestic or foreign market respectively. She then maximizes:

\[
\max_{\tilde{P}_{H,t}(j), \{y_{H,t}(j)\}_{t=0}^\infty} \sum_{s=0}^{\infty} E_t \left( \beta \theta_H^s \right) \lambda_{t+s} \left( \frac{\tilde{P}_{H,t}(j)}{P_{t+s}} - m c_{t+s} \right) y_{H,t+s}(j) 
\]

(16)

when producing for the domestic market, or

\[
\max_{\tilde{P}_{H,t}(j), \{y_{H,t}(j)\}_{t=0}^\infty} \sum_{s=0}^{\infty} E_t \left( \beta \theta_H^s \right) \lambda_{t+s} \left( \frac{\tilde{P}_{H,t}(j) S_{t+s}}{P_{t+s}} - m c_{t+s} \right) y_{H,t+s}(j) 
\]

(17)

when producing for the export market. When setting prices she faces downward sloping demand curves, that solve the problems of domestic and foreign final goods producers. In the
Consequences for DSGE models

equations above profits are evaluated according to the households (i.e. the owners) marginal utility of consumption, \( \tilde{P}_{H,t}(j) \) and \( \tilde{P}_{H,t}^{*}(j) \) are the new prices set on the domestic and foreign market by those firms that are allowed to change their price and \( mc_t \) is the real marginal cost.

**Monetary policy and market clearing**

The central bank follows a standard Taylor rule (variables without time indices denote steady state levels)

\[
\frac{R_t}{R} = \left( \frac{R_{t-1}}{R} \right)^{\gamma_R} \left[ \left( \frac{\pi_t}{\pi} \right)^{\gamma_\pi} \left( \frac{y_t}{y} \right)^{\gamma_y} \right]^{1-\gamma_R}
\]

(18)

where \( \gamma_R \), \( \gamma_\pi \) and \( \gamma_y \) are parameters and \( y_t \) denotes real GDP. The model is closed with a balance of payments equation and standard market clearing conditions.

**Calibration**

The calibration strategy is subordinated to the main goal of this section, to document the working of the nonlinear risk premium function in a small open economy. Given this goal the calibration of structural parameters is fully symmetric, the only difference being the size of the two economies (so that one is large and closed and the other small and open). Consequently the calibration reflects rather a generic than a specific small and large economy. In particular Calvo probabilities and habits are set to .75, the intertemporal elasticity of substitution is 2, the smoothing parameter in the Taylor rule is .75, the response to inflation 2 and the response to output .125, roughly in line with much of the empirical DSGE literature Smets and Wouters (2005); Adolfson et al. (2007). The elasticity of substitution between home and imported goods in the final aggregate is set to 4 (which implies \( \mu = 1.33 \)). The small economy is assumed to produce 1% of world GDP and its openness (share of imports in final good) is calibrated at 30%. Calibrated parameters are presented in Table 6.

### 4.3 Steady state issues

Let us start with the steady state. To better understand what the relationship between the risk premium and the NFA position implies for the model let us consider the UIP condition and risk premium equation in the steady state. The former boils down to (non-indexed variables denote steady state levels)

\[
\frac{R}{\pi} = \rho \frac{R^*}{\pi^*}
\]
Substituting for \( R \) and \( R^* \) from the steady state consumption Euler equations at home and abroad yields the relationship between the risk premium and rates of time preference:

\[
\rho = \frac{\beta^*}{\beta}
\]

Given the link between the NFA position and the risk premium (7) a balanced steady state NFA position is consistent only with equal rates of time preference. On the other hand non-zero debt is compatible only with diverging levels of patience. Importantly, with a reasonably parametrized risk premium function diverging time preference rates imply a non-degenerate steady state with a plausible NFA position. For instance assuming \( \beta^* = .99 \) and \( \beta = .985 \) (i.e. an annualized two percent premium) implies an annualized steady state debt-to-GDP ratio of roughly 100%. For comparison, the elasticity estimated by Garcia-Cicco et al. (2010) for Argentina would imply a 4% debt-to-GDP ratio in this case.

Diverging rates of time preference have not received much attention in the literature yet. However, as shown by Falk et al. (2015) time preferences differ substantially between countries. This may have important consequences for a broad range of macroeconomic issues, including economic growth (Dohmen et al., 2015), monetary policy (Fagan and Gaspar, 2007) or external imbalances. A simple but well parametrized link can offer a useful shortcut to analyze such problems.

4.4 Model dynamics

The previous section explained how to generate a non-zero steady state NFA position. In the current section we check how this affects the model dynamics. Since the risk premium elasticity depends on debt, responses to shocks will depend on the debt level as well. The goal of this section is to understand the mechanism and to verify whether the differences are significant.\(^4\) We consider two shocks - a standard supply shock to productivity, and a standard demand shock to preferences.

Figure 5 presents the reaction of the small economy to a negative productivity shock that generates a 2.5% decline in output. Since households smooth consumption and adjusting investments is costly both these variables decline by less than output. The impact is smoothed out thanks to net exports which decline, as a consequence foreign debt increases. Here the stories begin to differ depending on the premium elasticity. If the elasticity is low the premium increases only slightly. As a result the economy is not prevented to take more debt - net exports and NFA decline strongly and consumption and investments decline much

\[\text{The simulations presented below use the linear relationship (8) and (somewhat counterfactually) assumes zero debt in steady state. This technical assumption allows us to concentrate on the role of the slope, separating it from the impact of interest payments on past debt. Nevertheless, we will call the low (high) elasticity economy low (high) debt economy.}\]
Consequences for DSGE models

less than for the high-debt economy. Interestingly, for the productivity shock the domestic demand vs. net exports effect cancel out so that the impact of the shock on output is similar in both cases.

After a demand (preference) shock (Figure 6) consumption rises, one of the consequences being higher imports and rising foreign debt. In the low-elasticity economy this generates only a moderate increase of the risk premium. If the elasticity is high the risk premium rises more sharply. As a consequence the interest rate (not shown) increases by more, crowding out investments. In contrast to the productivity shock, now domestic demand and net exports do not cancel out, so that also GDP reacts differently for the two economies.

While the specific patterns clearly depend on the shock, two common conclusions can be drawn. First, the reactions may differ substantially, depending on the slope of the risk premium function. Second, the differences for national account components are more pronounced than for GDP. In general, the higher steady state debt, the stronger the impact of shocks on the domestic economy and the weaker on net exports.

4.5 Stochastic simulations

Last but not least we check how the varying slope of the risk premium function affects the volatility of selected variables. To some degree this can already be inferred from the impulse responses, however here we are able to present the findings not only for the two slopes that have been estimated, but also - for their wider range. Figures 7 and 8 document the evolution of standard deviations for consumption, investment, output and foreign debt as the slope of the risk premium function increases. Simulations are based on the linear relationship (8). For convenience, the volatility for $\psi_5 = 0.0001$, being our estimate for the low-debt economy, has been normalized to one.

In line with what can be expected, for both shocks the volatility of debt declines as the slope goes up - in this sense the economy becomes more similar to a closed one. For both shocks the volatility of investment increases, while the volatility of output remains relatively unaffected. This confirms the findings from the impulse response analysis - when the economy faces a higher slope of the risk premium function it finds it harder to smooth domestic variables (consumption, investment) at the cost of more volatile net exports. The main message from this Section is however quantitative, not qualitative. The slope affects at least some volatilities to a significant degree (for instance investment is 35% more volatile at $\psi_5 = 0.0012$ than at $\psi_5 = 0.0001$.)
5 Conclusions

This paper explores the nonlinear relationship between the country risk premium and its net foreign asset position. This nonlinearity is of particular importance since it may lead countries into debt traps. If risk premia initially increase slowly with worsening NFA positions and then suddenly jump the country may not be able to serve its foreign debt anymore. Moreover, the resulting sharp increase in financing costs may cause an economic recession. Greece could serve as a recent example of such unpleasant developments.

We estimate a nonlinear panel model based on data from 41 advanced and emerging economies. Our specification is flexible enough to allow for a wide range of nonlinearities. The data favors a nonlinear relationship with a relatively fast transition between low and high elasticity regimes. For positive and mildly negative NFA positions the risk premium elasticity is only slightly negative. However, once NFA worsens further the elasticity decreases substantially. The strongest impact is experienced for NFA below -74 % of annual GDP.

An important by-product of our estimation is a risk premium - foreign debt relationships that can be applied in DSGE models. Such a relationship has for a long time constituted an important ingredient of small open economy DSGE models. However, its calibration was supposed to provide model stability rather than reflect the elasticities found in the data. Our paper offers an appropriate calibration.

Moreover, we show on the basis of a standard two-economy DSGE model that taking into account the nonlinear risk premium - NFA relationship has important consequences for such models. First, it allows to take into account diverging rates of time preference in a way that is consistent with a well parametrized steady state. Second, we show that model dynamics and its stochastic properties differ significantly depending on the steady state NFA position. In particular, the higher steady state debt the stronger the impact of shocks on the domestic economy and the weaker on net exports.

Note: The numbers in column (1) and (2) refer to PSTR model with exponential transition function with fixed effects. The model in column (1) has been estimated with OLS while the model in column (2) with IV estimator. The numbers in columns (3) and (4) stand for parameter estimates for the models with period dummies estimated respectively with OLS and IV method. The values in columns (5) and (6) refer to models, which allow for different threshold level for NFA position for emerging and advanced economies. This difference is captured by the AE dummy variable. The detailed description of control variables: see Section 2. HAC standard errors in parentheses. *** p<0.01, ** p<0.05, * p<0.1.

### Figure 1: Interest rate spreads and NFA positions

![Interest rate spreads and NFA positions](image-url)
Figure 2: Examples of risk premium - NFA relationship with logistic transition function

Figure 3: Examples of risk premium - NFA relationship with exponential transition function
Figure 4: The estimated semi-elasticity of the risk premium with respect to the net foreign asset to GDP ratio

Figure 5: Impulse responses to productivity shock

Note: blue, solid line - low debt to GDP ratio ($ψ = 0.0001$). Red, dashed line - high debt to GDP ratio ($ψ = 0.0012$). All variables presented as deviation from steady state. GDP, consumption, investments and real exchange rate expressed in percent. Inflation and risk premium in annualized percentage points. Debt and net exports in percent of GDP.
Figure 6: Impulse responses to preference shock

Note: blue, solid line - low debt to GDP ratio ($\psi_5 = 0.0001$). Red, dashed line - high debt to GDP ratio ($\psi_5 = 0.0012$).
All variables presented as deviation from steady state. GDP, consumption, investments and real exchange rate expressed in percent. Inflation and risk premium in annualized percentage points. Debt and net exports in percent of GDP.

Figure 7: Volatility for various slopes (productivity shocks)

Note: slope of risk premium function ($\psi_5$) on horizontal axis. Standard deviation of consumption, investment, output and debt on vertical axis, normalized to unity for $\psi_5 = 0.0001$ (i.e. slope estimated for low debt economies).
Figure 8: Volatility for various slopes (productivity shocks)

Note: slope of risk premium function ($\psi^5$) on horizontal axis. Standard deviation of consumption, investment, output and debt on vertical axis, normalized to unity for $\psi^5 = 0.0001$ (i.e. slope estimated for low debt economies).
